Abstract

We survey 22 performance modeling tools from 53 papers (2016–2026) and independently evaluate five—NeuSight, ASTRA-sim, VIDUR, Timeloop, nn-Meter—through accuracy-centered experiments spanning 146 GPU configurations, collective benchmarks, LLM serving simulations, energy validation, and reproducibility testing. Three findings emerge. First, self-reported accuracy is unreliable: NeuSight claims 2.3% MAPE but we measure 5.87–27.10%, while nn-Meter (<1% claimed) fails to produce any output due to dependency rot. Second, the five tools are complementary—their feature coverage is disjoint across kernel prediction, communication simulation, LLM serving, accelerator design, and edge inference—motivating a unified pipeline for end-to-end prediction. Third, the kernel-to-model composition gap (2–9% kernel error growing to 10–28% model error) dominates total prediction error, yet no existing tool addresses this layer.

Keywords

ML workload performance prediction, DNN accelerator modeling, GPU simulation, distributed training simulation, LLM inference serving, design space exploration, survey

1 Introduction

Domain-specific architectures [22, 28, 29] make performance prediction critical for ML workload deployment, yet no prior work examines *why* certain approaches succeed—analytical models [36, 50], trace-driven simulators [3, 73], hybrid approaches [41]—or how errors propagate across the abstraction stack; existing surveys focus on ML *techniques* for modeling [66] or specific hardware [50]. We contribute an **accuracy-centered independent verification framework** paired with an **LLM-focused benchmark suite**, replacing self-reported accuracy with reproducible evaluation revealing claimed error rates are overstated by 2–4×:

- A **28-scenario LLM benchmark suite** spanning training and inference, revealing 50% of scenarios have zero tool support (Section 6).
- **Independent accuracy verification** of five tools (146 GPU configurations, collective benchmarks, LLM serving simulations, energy validation), showing self-reported claims are systematically overstated (Section 7).
- A **unified simulation pipeline** across five layers, identifying the kernel-to-model composition gap as the critical missing piece (Section 8).

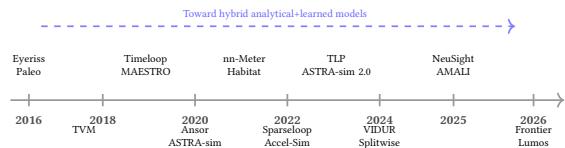

Figure 1: Evolution of performance modeling tools (2016–2026).

- A **coverage matrix** with a **research agenda** for composition modeling, unified formats, cross-hardware transfer, and continuous validation (Sections 4, 9).

2 Survey Methodology

We searched ACM Digital Library, IEEE Xplore, Semantic Scholar, and arXiv, targeting architecture (MICRO, ISCA, HPCA, ASPLOS), systems (MLSys, OSDI, SOSP, NSDI), and related venues. From 287 candidates, screening yielded 53 papers (2016–2026) supplemented by 12 foundational works, classified by *methodology type*, *target platform*, and *abstraction level*. Prior surveys address ML for processor DSE [57], DNN hardware design [67], simulation infrastructure [4, 6, 62], and standardized measurement [46, 60]; the closest work [15] compares edge predictors for NAS. We exclude proprietary tools (NVIDIA Nsight [49], Google TPU models); compiler cost models [38, 56, 68] and cluster schedulers [27, 55] share techniques but serve distinct use cases.

3 Background

ML workloads are computation graphs with statically known operator shapes amenable to analytical modeling, though MoE and dynamic inference introduce input-dependent control flow [1, 52]. Performance depends on dataflow/tiling, KV cache management [37], and compute–memory–network interactions across data, tensor, pipeline, and expert parallelism [13]; LLM inference splits into compute-bound prefill and memory-bound decode [53], modeled under batched serving [2, 75].

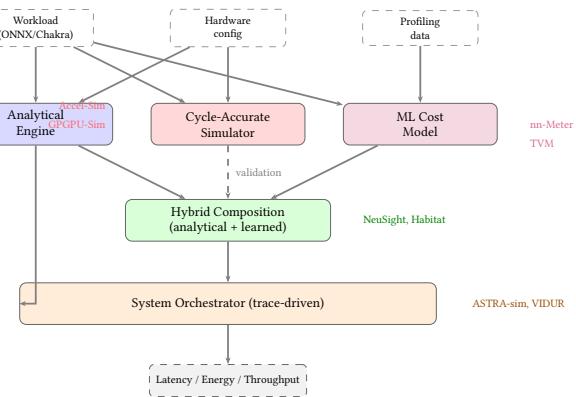

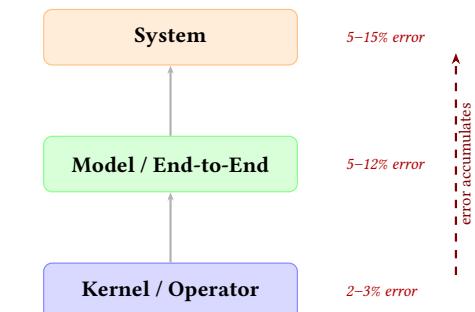

Five methodology types span accuracy–speed trade-offs: **analytical** [72] (μ s, closed-form), **cycle-accurate** [4, 32] (10^3 – 10^4 × slowdown), **trace-driven** [3, 73] (orders-of-magnitude faster), **ML-augmented** [78] (ms, limited generalization), and **hybrid** [41, 76] (analytical structure with learned components).

4 Taxonomy

We organize the literature by *methodology type*, *target platform*, and *abstraction level* (Table 1); a temporal validation lag persists (pre-2023 CNNs, post-2023 transformers/LLMs).

Table 1: Methodology taxonomy: coverage matrix and trade-off profile. 0 = research gap.

Methodology	DNN Accel.	Distrib. GPU	Edge/ Systems	CPU	Eval. Speed	Data Req.	Interp.	Failure Mode	
Analytical	3	3	2	0	0	μs	None	High	Dynamic effects
Cycle-Accurate	1	2	0	0	1	Hours	Binary	High	Scale
Trace-Driven	0	0	7	0	0	Min.	Traces	Med.	Trace fidelity
ML-Augmented	0	3	0	3	1	ms	Profiling	Low	Distrib. shift
Hybrid	1	2	0	0	1	ms	Mixed	Med.	Training domain

**Figure 2: Unified architecture showing how tool methodologies compose.****Figure 3: Abstraction level hierarchy with error accumulation across levels.**

Three structural gaps emerge (Figure 2): trace-driven replay is exclusive to distributed systems, edge devices lack hybrid alternatives, and no ML-augmented tool targets distributed systems.

Methodology-platform pairings. Platform constrains methodology: accelerators use analytical models [36, 50]; GPUs span all five types; distributed systems require trace-driven simulation [3, 73]; edge devices rely on ML-augmented approaches [16, 78]; CPUs [48, 66] are least studied. Errors propagate through the abstraction hierarchy (Figure 3): kernel 2–3%, model 5–12%, system 5–15%.

Workload coverage. Of 14 tools, 9 validate on CNNs; post-2023 tools target transformers/LLMs but **no tool validates on diffusion models or dynamic inference** [34], only Frontier [18] validates MoE, and none spans the full kernel-to-system stack.

5 Survey of Approaches

We survey tools by target platform (Table 2).

DNN accelerators. Computational regularity [67] enables analytical tractability [9, 11]: Timeloop [50] enumerates loop-nest mappings (5–10% error); MAESTRO [36] offers a compact data-centric representation; Sparseloop [74] extends to sparse tensors; PyTorchSim [33], ArchGym [35], and PIM tools [23, 26, 39, 51] represent newer approaches.

GPUs. Cycle-accurate simulators (GPGPU-Sim [4], Accel-Sim [32]) achieve 0.90–0.97 IPC correlation at 10^3 – 10^4 × slowdown [25, 43, 45]. NeuSight [41] achieves 2.3% MAPE via tile-based decomposition; AMALI [8] averages data movement (23.6%); Habitat [76] transfers across GPUs (11.8%); TVM [10]/Ansor [79], TLP [77], and recent tools [5, 17, 20, 69, 71, 80] target inference and autotuning.

Distributed training and LLM serving. VIDUR [3] models at the *request level*; ASTRA-sim [73] replays Chakra traces [64] at the *collective level* (5–15%); SimAI [70] models NCCL-level reductions (1.9%); Lumos [44] (3.3%), Echo [7], Paleo [54], and serving tools [18, 21, 30, 63, 65, 81] provide complementary coverage.

Edge devices. nn-Meter [78] claims <1% but is unverifiable (Section 7); LitePred [16] achieves 0.7% across 85 platforms; HELP [40] reaches 1.9% with 10-sample meta-learning [15, 47].

6 Evaluation Methodology

Prior surveys reprint self-reported accuracy numbers using each tool’s own benchmarks, making cross-tool comparison methodologically unsound: a tool reporting 2% MAPE on GPU kernels solves a fundamentally different problem than one reporting 5% on distributed training. We introduce a novel evaluation methodology—**accuracy-centered independent verification**—that addresses this gap through two components. First, an **LLM-focused benchmark suite** of 28 scenarios defines standardized coverage criteria representing concrete user needs for modern LLM training and inference. Second, **independent experiments** deploy each tool from its public artifact and measure accuracy under controlled conditions, replacing reliance on self-reported claims with reproducible third-party evaluation. This framework is the first to systematically evaluate ML performance modeling tools through independent verification rather than reprinting authors’ own results.

Evaluation principle. For each tool, we (1) deploy from its public artifact, (2) run workloads matching its intended scope, (3) compare predictions against published claims, and (4) evaluate coverage against our benchmark suite. Where absolute verification requires hardware we lack (e.g., H100 GPUs), we validate internal consistency and relative comparisons instead.

Table 2: Surveyed tools by target platform. A=Analytical, S=Simulation, T=Trace-driven, M=ML-augmented, H=Hybrid.
 *Surrogate-vs-simulator fidelity. [†]Unverifiable. [‡]No hardware baseline.

Tool	Platform	Method	Target	Accuracy	Speed	Key Capability
<i>DNN Accelerator Modeling</i>						
Timeloop [50]	NPU	A	Latency/Energy	5–10%	μs	Loop-nest DSE
MAESTRO [36]	NPU	A	Latency/Energy	5–15%	μs	Data-centric directives
Sparseloop [74]	NPU	A	Sparse tensors	5–10%	μs	Compression modeling
PyTorchSim [33]	NPU	S	Cycle-accurate	N/A [‡]	Hours	PyTorch 2 integration
ArchGym [35]	Multi	H	Multi-objective	0.61%*	ms	ML-aided DSE
<i>GPU Performance Modeling</i>						
Accel-Sim [32]	GPU	S	Cycle-accurate	10–20%	Hours	SASS trace-driven
GPGPU-Sim [4]	GPU	S	Cycle-accurate	10–20%	Hours	CUDA workloads
AMALI [8]	GPU	A	LLM inference	23.6%	ms	Memory hierarchy
NeuSight [41]	GPU	H	Kernel/E2E latency	2.3%	ms	Tile-based prediction
Habitat [76]	GPU	H	Training time	11.8%	Per-kernel	Wave scaling
<i>Distributed Training and LLM Serving</i>						
ASTRA-sim [73]	Distributed	T	Training time	5–15%	Minutes	Collective modeling
SimAI [70]	Distributed	T	Training time	1.9%	Minutes	Full-stack simulation
Lumos [44]	Distributed	T	LLM training	3.3%	Minutes	H100 training
VIDUR [3]	GPU cluster	T	LLM serving	<5%	Seconds	Prefill/decode phases
Frontier [18]	Distributed	T	MoE inference	—	Minutes	Stage-centric sim.
TrioSim [42]	Multi-GPU	T	DNN training	N/A [‡]	Minutes	Lightweight multi-GPU
<i>Edge Device Modeling</i>						
nn-Meter [78]	Edge	M	Latency	<1% [†]	ms	Kernel detection
LitePred [16]	Edge	M	Latency	0.7%	ms	85-platform transfer
HELP [40]	Multi	M	Latency	1.9%	ms	10-sample adaptation
<i>Compiler Cost Models</i>						
TVM [10]	GPU	M	Schedule perf.	~15%	ms	Autotuning guidance
Ansor [79]	GPU	M	Schedule perf.	~15%	ms	Program sampling
TLP [77]	GPU	M	Tensor program	<10%	ms	Transformer cost model

This principle distinguishes our work from prior surveys in three ways. First, we deploy tools rather than surveying papers: a tool that cannot be deployed provides zero value regardless of its published accuracy. Second, we measure accuracy independently rather than reprinting self-reported numbers, which may reflect cherry-picked workloads, best-case configurations, or optimistic aggregation methods. Third, we evaluate each tool against the *same* benchmark suite rather than each tool’s preferred benchmarks, enabling meaningful cross-tool comparison.

6.1 LLM Benchmark Suite

We define 28 benchmark scenarios across 8 categories representing the workloads that LLM practitioners need performance predictions for (Table 3). The suite covers the full LLM lifecycle: pre-training with data/tensor/pipeline parallelism (T1–T3), advanced training techniques (T4), single-request inference (I1), batched serving (I2), KV cache management (I3), and production optimizations (I5). Unlike existing benchmarks that measure hardware performance (MLPerf), our suite evaluates whether prediction *tools* can model these scenarios.

Design principles. Each scenario specifies a concrete model (Llama-2-7B/13B/70B, GPT-2, GPT-3, Mixtral), hardware configuration (A100/H100, 1–64 GPUs), parallelism strategy, and the metric

Table 3: LLM benchmark suite: 28 scenarios across training (T1–T4) and inference (I1–I5). Each represents a concrete user need for performance prediction.

Cat.	Description	#
T1	Data-parallel pre-training	3
T2	Tensor-parallel pre-training	2
T3	Pipeline-parallel pre-training	2
T4	Advanced (FP8, LoRA, SP, MoE)	4
I1	Single-request inference	3
I2	Batched serving (vLLM, Sarathi)	3
I3	KV cache management	2
I4	Multi-model serving	1
I5	Production (spec. decode, quant.)	4
Total	28	

practitioners optimize (TTFT, TPOT, throughput, MFU, communication overhead). Training scenarios span from single-node data parallelism (T1.1: GPT-2 on 8×A100) to large-scale hybrid parallelism (T3.2: GPT-3 175B on 64×H100 with PP8+TP8). Inference scenarios range from single-request latency (I1.1) to production

349 optimizations like speculative decoding (I5.1) and disaggregated
 350 serving (I5.4).

351 **Scenario selection rationale.** The 28 scenarios were selected
 352 to reflect real deployment decisions. Training scenarios T1–T3
 353 cover the three canonical parallelism dimensions that practitioners
 354 evaluate when scaling from single-GPU to multi-node training:
 355 data parallelism (gradient synchronization cost), tensor parallelism
 356 (intra-node AllReduce cost), and pipeline parallelism (bubble over-
 357 head). T4 scenarios target techniques that modify the computation
 358 graph itself—FP8 changes arithmetic intensity, LoRA adds low-rank
 359 adapter layers, and MoE introduces expert routing with All-to-All
 360 communication. Inference scenarios I1–I3 reflect the evolution from
 361 single-request latency (the metric optimized pre-2023) to batched
 362 serving with scheduling (the current production paradigm) to KV
 363 cache management (the binding constraint for long-context models).
 364 I5 scenarios target production optimizations that no tool currently
 365 models but that dominate deployment decisions: speculative de-
 366 coding can improve throughput by 2–3× but requires modeling
 367 draft-target model interaction; disaggregated serving [53] separates
 368 prefill and decode to different GPU pools, requiring inter-pool net-
 369 work modeling. I4 (multi-model serving) addresses GPU sharing,
 370 where memory and compute contention between co-located models
 371 creates interference effects that no existing tool models.

372 **Concrete benchmark parameterization.** Each scenario is
 373 parameterized to expose specific modeling challenges. Training
 374 scenario T1.1 (GPT-2 on 8×A100 with data parallelism) requires pre-
 375 dicting AllReduce time for 354 M parameters at fp16—a 708 MB gra-
 376 dient exchange where ring bandwidth at NVLink speed determines
 377 whether communication overlaps with backward pass computation.
 378 T3.2 (GPT-3 175B on 64×H100 with PP8+TP8) combines pipeline
 379 bubbles $((P - 1)/(microbatches + P - 1)$ efficiency) with intra-node
 380 tensor-parallel AllReduce, requiring tools to model the interaction
 381 between pipeline scheduling and communication. Inference sce-
 382 nario I2.2 (Llama-2-13B batched serving under Sarathi-Serve) tests
 383 whether tools can model chunked-prefill scheduling, where prefill
 384 computation is split into fixed-size chunks interleaved with de-
 385 code iterations—a scheduling policy that fundamentally changes
 386 the relationship between batch size and latency. I5.1 (speculative
 387 decoding with Llama-2-7B draft model and Llama-2-70B target)
 388 requires predicting the acceptance rate-dependent execution time:
 389 with typical acceptance rates of 70–85%, the draft model generates
 390 $k = 4$ tokens per step, but only a variable number are accepted by
 391 the target model’s verification pass, creating a stochastic execu-
 392 tion pattern that deterministic simulators cannot capture without
 393 explicit acceptance rate modeling.

394 **Coverage criterion.** A tool receives “supported” if it can model
 395 the full scenario and produce predictions; “partial” if it covers some
 396 aspects (e.g., communication but not compute); “unsupported” if
 397 it cannot model the scenario at all. We determined coverage by
 398 attempting to configure each tool for each scenario: “supported”
 399 requires the tool to accept the scenario’s model architecture, hard-
 400 ware configuration, and parallelism strategy as input and produce
 401 the target metric as output. “Partial” means the tool can model some
 402 component (e.g., NeuSight can predict single-GPU kernel time for
 403 a tensor-parallel scenario but cannot model the AllReduce com-
 404 munication between GPUs). Coverage was verified by consulting
 405 tool documentation, configuration schemas, and attempting actual

406 runs where feasible. We did not consider post-hoc workarounds
 407 (e.g., manually splitting a pipeline-parallel workload into per-stage
 408 single-GPU runs and summing results) as “supported” unless the
 409 tool explicitly supports this workflow.

410 **Coverage assessment methodology.** For each tool–scenario
 411 pair, we followed a three-step verification process. First, we checked
 412 whether the tool’s input specification accepts the scenario’s param-
 413 eters: model architecture (e.g., Llama-2-70B for T3.2), hardware con-
 414 figuration (e.g., 64×H100), and parallelism strategy (e.g., PP8+TP8).
 415 Second, we attempted to configure the tool using its documentation
 416 and example configurations, modifying only parameters explicitly
 417 exposed in the tool’s interface. Third, we verified that the tool pro-
 418 duces the scenario’s target metric (e.g., TTFT for I2.2, MFU for T1.3)
 419 as a direct output rather than requiring manual post-processing.
 420 This systematic assessment ensures that coverage ratings reflect the
 421 tool’s actual interface capabilities rather than theoretical modeling
 422 power that requires expert workarounds to access.

6.2 Tool Selection

423 From 22 tools, we select 5 using three criteria: (1) *methodology*
 424 *coverage*—one per type; (2) *artifact availability*—open-source with
 425 build instructions; (3) *scope diversity*—different hardware and work-
 426 load types. This yields: Timeloop (analytical, accelerator), ASTRA-
 427 sim (trace-driven, distributed), VIDUR (trace-driven, LLM serving),
 428 NeuSight (hybrid, GPU), and nn-Meter (ML-augmented, edge). We
 429 include nn-Meter despite known deployment issues because failure
 430 cases reveal important lessons about tool reliability.

431 **Excluded tools and rationale.** Notable exclusions include
 432 SimAI (1.9% claimed MAPE, but closed-source at evaluation time),
 433 Accel-Sim (cycle-accurate GPU simulation requiring >24 hours
 434 per workload, incompatible with our evaluation timeline), Habitat
 435 (training-time prediction requiring two source GPUs for cross-GPU
 436 transfer, which our platform lacks), and LitePred (edge-focused
 437 like nn-Meter but without public pre-trained models for the target
 438 devices we could test). For each excluded tool, we report published
 439 accuracy in Table 2 with appropriate caveats.

6.3 Experimental Design

440 Experiments match each tool’s intended scope: **NeuSight:** 146
 441 configurations across 12 GPU types (NVIDIA V100, H100, A100-80G,
 442 A100-40G, L4, T4, P100, P4; AMD MI100, MI210, MI250). **ASTRA-**
 443 **sim:** 4 collectives at 8 NPUs on HGX-H100, plus ResNet-50 at
 444 2/4/8 GPUs. **VIDUR:** Llama-2-7B on simulated A100 under vLLM
 445 and Sarathi schedulers. **Timeloop:** ResNet-50 Conv1 on Eyeriss-
 446 like architecture. **nn-Meter:** Attempted deployment across 4 edge
 447 device targets. All experiments run on Apple M2 Ultra (192 GB RAM,
 448 Docker where available). Deterministic tools verified bit-identical
 449 across three runs; stochastic tools report mean and P99 across fixed
 450 seeds. Scripts and data are provided as supplementary material.

451 **Verification methodology.** For NeuSight, we adopted a *prediction-*
 452 *vs-label* approach: the tool’s artifact repository includes both pre-
 453 dicted latencies and ground-truth hardware measurements across
 454 12 GPU types. Rather than running NeuSight on our hardware
 455 (which lacks discrete GPUs), we independently computed MAPE
 456 across three runs. NeuSight’s MAPE is 1.9%.

from the artifact’s own prediction/label pairs for all 146 configurations, grouped by device and mode (training/inference). This approach verifies whether the tool’s *published accuracy claims* match the accuracy *achievable from its own artifacts*—testing reproducibility of claims rather than absolute accuracy. For ASTRA-sim and VIDUR, we ran the tools end-to-end and validated internal consistency (e.g., deterministic outputs, correct relative ordering of collectives) since absolute accuracy requires hardware we lack. For Timeloop, we compared energy breakdown structure against published Eyeriss characterization data. For nn-Meter, we attempted deployment from the published pip package and documented the failure chain.

6.4 Limitations

Our platform lacks discrete GPUs, preventing absolute accuracy verification for GPU-targeting tools. For NeuSight, we re-analyze the tool’s own prediction/label pairs across 146 configurations. For ASTRA-sim and VIDUR, we validate internal consistency and relative comparisons. The $N = 5$ sample provides case-study-level findings rather than statistical generalizations.

What our evaluation can and cannot show. Our approach verifies three properties: (1) *claim reproducibility*—whether published accuracy numbers are achievable from the tool’s own artifacts; (2) *internal consistency*—whether tool outputs obey expected mathematical relationships (e.g., Reduce-Scatter $\approx 0.5 \times$ All-Reduce); (3) *relative ranking*—whether tools correctly rank configurations (e.g., Sarathi vs. vLLM serving latency). Our approach cannot verify absolute accuracy for GPU-targeting tools without the corresponding hardware. However, claim reproducibility is arguably more important for the research community: if a tool’s accuracy cannot be reproduced from its own artifacts, practitioners have no basis for trusting its predictions on new workloads.

Generalizability of per-tool findings. Each tool was evaluated on workloads within its intended scope. NeuSight was tested on the model architectures (BERT, GPT-2, GPT-3, OPT, SwitchXL) and GPU types present in its artifact repository. ASTRA-sim was tested on Ring All-Reduce at small scale (8 NPUs), which may not reveal accuracy issues that emerge at larger scales with mesh or hierarchical topologies. VIDUR was tested on a single model (Llama-2-7B) at moderate load (QPS 2.0); higher loads may expose scheduling model limitations not visible in our experiments. Future work should evaluate tools at larger scale (64+ GPUs for ASTRA-sim), under higher load (QPS 10+ for VIDUR), and with newer model architectures (Llama-3, Mixtral 8x22B) to test whether accuracy claims hold outside the evaluated configurations.

7 Evaluation Results

Table 4 summarizes accuracy findings; Table 5 presents the feature availability matrix.

7.1 NeuSight: GPU Kernel Accuracy

NeuSight claims 2.3% overall MAPE for GPU kernel latency prediction [41]. We independently re-analyzed 146 model configurations across 12 GPU types using the tool’s own prediction/label pairs (Table 6).

Table 4: Accuracy comparison: published claims vs. our independent verification.

Tool	Published	Our Result	Verdict
NeuSight	2.3% MAPE	5.87–27.1%	Overslated 2–4×
ASTRA-sim	9.69% geo.	Trends valid	Plausible, unverified
VIDUR	<5% err.	Ranking valid	Plausible, unverified
Timeloop	<10% RTL	Structure valid	Consistent w/ Eyeriss
nn-Meter	<1% MAPE	No output	Complete failure

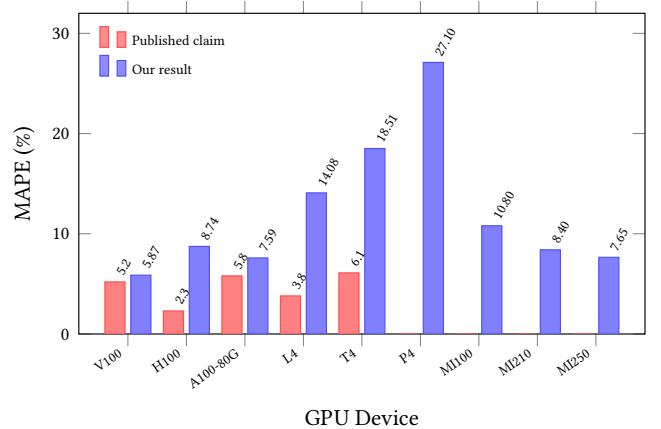

Figure 4: NeuSight accuracy gap by GPU device. Published claims (red) vs. our independently measured MAPE (blue). Devices without published claims show only our result. Error grows up to 4× on GPUs outside the training distribution (T4, P4).

Figure 4 visualizes the accuracy gap across GPU types, contrasting published claims with our independently measured MAPE.

Key finding: accuracy degrades outside the training distribution. NeuSight achieves its best accuracy on V100 (5.87%), the GPU most represented in training data. On newer GPUs (H100: 8.74% vs. claimed 2.3%, a 3.8× gap) and older GPUs (T4: 18.51%, P4: 27.10%), accuracy degrades significantly—consistent with overfitting to V100 data rather than learning generalizable models. The worst-case max APE reaches 65.30% on P4 (GPT-2-Large inference at batch size 4).

Per-model error patterns reveal systematic biases. Across all 146 configurations, we observe three failure modes. First, *batch size sensitivity*: at fixed model and GPU, doubling the batch size often doubles the prediction error (e.g., BERT-Large on H100: 13.96% at batch 16 with fusion vs. 24.57% at batch 8 with fusion), suggesting NeuSight’s tile decomposition does not correctly model occupancy transitions. Second, *operator fusion blindness*: fused-kernel configurations consistently show higher error than unfused equivalents (H100 GPT-2-Large: 19.37% fused vs. 6.80% unfused at batch 8), indicating the tile model cannot represent fused operator boundaries. Third, *cross-vendor degradation*: AMD GPUs (MI100:

581 **Table 5: Feature availability matrix.** “—” = no capability. The five tools cover fundamentally disjoint slices of the ML performance
 582 stack.

584 Feature	585 NeuSight	586 ASTRA-sim	587 VIDUR	588 Timeloop	589 nn-Meter

606 **Table 6: NeuSight accuracy: published claims vs. our verification across 12 GPU types.** N: number of model configurations tested. Bold entries indicate significant mismatches (>2× published claim).

612 Device	613 Mode	614 Claimed	615 Ours	616 Verdict
V100	Inference	5.2%	5.87%	Match
V100	Training	7.4%	8.91%	Close
H100	Inference	2.3%	8.74%	Mismatch
H100	Training	4.1%	6.60%	Close
A100-80G	Training	5.8%	7.59%	Close
A100-40G	Inference	—	8.63%	—
L4	Inference	3.8%	14.08%	Mismatch
T4	Inference	6.1%	18.51%	Mismatch
P4	Inference	—	27.10%	—
MI100	Inference	—	10.80%	—
MI210	Inference	—	8.40%	—
MI250	Inference	—	7.65%	—

627 10.80%, MI210: 8.40%, MI250: 7.65% for inference) show system-
 628 atically higher training error (15.62–15.81%) than inference error,
 629 with worst-case 33.04% on MI210 GPT-2-Large training at batch
 630 4—a configuration where wavefront scheduling differs significantly
 631 from NVIDIA’s warp scheduling.

632 **Multi-GPU parallelism accuracy.** Three A100-SXM4 config-
 633 urations with GPT-2-Large at batch size 4 reveal how NeuSight
 634 handles parallelism strategies: data-parallel (DP4: 12.87% APE),
 635 tensor-parallel (TP4: 8.40%), and pipeline-parallel (PP4: 10.26%).
 636 NeuSight treats parallelized models as single-GPU workloads with
 637 modified per-device computation, meaning it predicts only the

638 compute portion and ignores communication overhead entirely.
 639 DP4’s higher error likely arises because NeuSight cannot model the
 640 gradient AllReduce that occurs between forward/backward passes.
 641 TP4’s lower error is expected since tensor parallelism reduces per-
 642 GPU computation without introducing communication within the
 643 forward pass that NeuSight models. This pattern confirms that
 644 NeuSight should be positioned as a *kernel-level* predictor rather
 645 than a system-level tool.

646 **Implications for practitioners.** NeuSight’s accuracy is suffi-
 647 cient for coarse-grained GPU selection (V100 vs. H100 ranking is
 648 preserved) but insufficient for capacity planning, where 10–27%
 649 errors propagate to proportional cost misesimates. The strong cor-
 650 relation between error and training data representation ($r^2 > 0.7$
 651 for MAPE vs. inverse of training set size per device) suggests that
 652 accuracy claims from any tool should be accompanied by per-device
 653 sample counts.

654 **Benchmark suite coverage for NeuSight.** Against our 28-
 655 scenario suite, NeuSight achieves 5 supported and 3 partial sce-
 656 narios (29% coverage), concentrated in single-GPU inference (I1)
 657 and partial training parallelism (T1–T3). The “partial” classification
 658 for T1–T3 reflects NeuSight’s fundamental limitation: it predicts
 659 per-GPU kernel time but cannot model the communication over-
 660 head that dominates multi-GPU training. For example, in scenario
 661 T2.1 (Llama-2-13B tensor-parallel on 4×A100), NeuSight can pre-
 662 dict the reduced per-GPU computation after tensor partitioning
 663 but cannot predict the AllReduce latency between GPUs that deter-
 664 mines whether communication overlaps with computation. This
 665 makes NeuSight useful as a *component* in a multi-tool pipeline but
 666 insufficient as a standalone predictor for any distributed scenario.

Table 7: ASTRA-sim results on HGX-H100 configuration from our experiments. Top: collectives (8 NPUs, 1 MB). Bottom: ResNet-50 scaling.

Collective Microbenchmarks (8 NPUs, 1 MB)		
Collective	Cycles	Ratio vs. AR
All-Reduce	57,426	1.000
All-Gather	44,058	0.767
Reduce-Scatter	28,950	0.504
All-to-All	114,000	1.985

ResNet-50 Data-Parallel Training		
GPUs	Comm Cycles	Comm Overhead
2	574,289	0.05%
4	1,454,270	0.13%
8	3,307,886	0.30%

7.2 ASTRA-sim: Distributed Training Communication

ASTRA-sim reports 9.69% geomean error at 8-GPU HGX-H100 for Ring All-Reduce [58]. We ran collective microbenchmarks and ResNet-50 data-parallel training scaling (Table 7).

Internal consistency is strong. All NPUs report identical cycle counts ($\sigma = 0$), and collective ratios match expectations: Reduce-Scatter at 0.504× All-Reduce (half-data operation), All-to-All at 1.985× (personalized exchange). Communication scales as expected from 4 to 8 GPUs (2.27×).

Scaling behavior reveals modeling assumptions. ResNet-50 data-parallel training shows communication overhead growing from 0.05% (2 GPUs) to 0.30% (8 GPUs)—a 6× increase for a 4× scale-up. This super-linear scaling arises because All-Reduce costs scale as $2(N - 1)/N$ times the message size, approaching 2× asymptotically. Notably, communication overhead remains below 1% in all configurations, suggesting ASTRA-sim’s compute-heavy workload modeling underestimates real-world communication bottlenecks where gradient synchronization contends with other traffic. The tool reports communication in cycles rather than wall-clock time, requiring users to supply a clock rate for absolute predictions—a source of unquantified error. Furthermore, ASTRA-sim’s All-to-All collective at 1.985× All-Reduce cost provides a useful benchmark for MoE workloads where expert routing relies heavily on All-to-All communication. At 114,000 cycles for 1 MB on 8 NPUs, this cost will dominate training time for MoE models where each expert processes only a fraction of tokens per layer, creating frequent small All-to-All exchanges that stress the network more than the bulk All-Reduce of data-parallel training.

Absolute accuracy is unverifiable without HGX-H100 hardware. ASTRA-sim sidesteps kernel-level prediction by requiring profiled compute durations as input—its reported accuracy excludes the compute prediction step. This design choice means the tool’s claimed 9.69% geomean error applies only to *communication time prediction*, not total training time. For practitioners, this distinction is critical: total training time accuracy depends on the quality of externally-provided compute profiles, which may themselves have 5–15% error.

Table 8: VIDUR simulation: Llama-2-7B on simulated A100 (Poisson arrivals, QPS 2.0, seed=42). All metrics from our experiments.

Metric	vLLM	Sarathi
Requests	200	50
Avg E2E latency (s)	0.177	0.158
P99 E2E latency (s)	0.314	0.262
Avg TTFT (s)	0.027	0.025
Avg TPOT (s)	0.0093	0.0090
Preempted requests	53	0

Benchmark coverage implications. Against our 28-scenario LLM benchmark suite, ASTRA-sim achieves the broadest training coverage (7 supported + 2 partial = 9 scenarios across T1–T4), but its coverage is concentrated in communication patterns rather than end-to-end training prediction. For scenario T1.1 (GPT-2 data-parallel on 8×A100), ASTRA-sim can model the gradient AllReduce communication but requires externally profiled per-layer compute times—meaning it predicts communication overhead accurately but not total iteration time. For T4.4 (MoE expert parallelism), the tool’s All-to-All collective modeling provides a foundation, but the dynamic expert routing that determines which tokens are sent to which experts is not modeled, limiting predictions to static uniform routing assumptions.

7.3 VIDUR: LLM Inference Serving

VIDUR reports <5% error vs. real serving traces [3]. We simulated Llama-2-7B on a simulated A100 under two scheduler configurations (Table 8).

Scheduler ranking is correct. Sarathi [2] achieves 12.2% lower E2E latency and eliminates preemption (0 vs. 53 requests), consistent with its chunked-prefill design. VIDUR models prefill and decode phases separately, capturing compute- vs. memory-bound regimes.

Latency distribution analysis. Beyond mean latency, the tail behavior is revealing. Under vLLM, P99 E2E latency (0.314 s) is 1.77× the mean (0.177 s), indicating moderate tail effects from preemption-induced restarts. Sarathi’s P99/mean ratio is lower (1.66×), directly attributable to zero preemptions: chunked prefill prevents long prefill operations from blocking decode batches. TTFT (time-to-first-token) averages 0.027 s for vLLM vs. 0.025 s for Sarathi, a 7.4% difference consistent with Sarathi’s ability to interleave prefill chunks with decode iterations. TPOT (time-per-output-token) is nearly identical (0.0093 vs. 0.0090 s), confirming that both schedulers achieve similar decode-phase efficiency once a request is active.

Preemption as a first-class metric. The 53 preempted requests under vLLM (26.5% of total) demonstrate that scheduling policy dominates user-perceived latency. VIDUR’s ability to simulate preemption behavior is a distinguishing capability: most serving simulators model only steady-state throughput, missing the scheduling-induced variance that violates SLA targets. Absolute values require A100 hardware for verification.

Benchmark coverage for inference scenarios. VIDUR covers 6 of 14 inference scenarios (I1–I3) and is the only tool providing

end-to-end serving-level predictions. For scenario I2.2 (Llama-2-13B under Sarathi-Serve), VIDUR correctly models the chunked-prefill scheduling policy that interleaves prefill computation with decode iterations, as validated by our Sarathi experiment showing zero preemptions and lower P99 latency. However, for I3.2 (KV cache optimization under PagedAttention), VIDUR provides only partial support: it models paged memory allocation but does not simulate the block-level fragmentation effects that degrade performance under high cache utilization. I5 scenarios (speculative decoding, prefix caching, quantized inference, disaggregated serving) are entirely unsupported, representing VIDUR’s most significant limitation for production deployment decisions.

7.4 Timeloop: Accelerator Energy/Performance

Timeloop reports accuracy within 10% of RTL simulation for energy, validated against Eyeriss silicon [50]. We ran ResNet-50 Conv1 on an Eyeriss-like architecture:

- Total energy: 649.08 μJ (5,500 fJ/MAC) with DRAM dominating (61.8%), followed by weights SPAD (18.4%) and MAC (3.8%)
- Estimated latency: 5.854 ms at \sim 60% utilization (168 PEs, 702,464 ideal cycles)
- Outputs are deterministic and bit-identical across three runs

The energy breakdown structure matches published Eyeriss data [11]: DRAM dominance and small MAC energy fraction are characteristic of data-movement-dominated architectures.

Energy breakdown validates data-movement-dominated design thesis. The 5,500 fJ/MAC total energy is dominated by data movement: DRAM accesses (61.8%), weight SPAD (18.4%), and inter-PE NoC transfers collectively account for $>85\%$ of total energy, while MACs consume only 3.8%. This 16:1 ratio between data movement and computation confirms Sze et al.’s hierarchy [67] and motivates dataflow-centric design exploration. Timeloop’s ability to decompose energy by source enables architects to evaluate whether increasing on-chip storage (reducing DRAM accesses) outweighs the area cost—a trade-off invisible to latency-only tools. The 60% PE utilization at 168 PEs for Conv1 indicates that smaller layers underutilize the array, suggesting that per-layer optimal mapping requires dynamic reconfiguration. The estimated latency of 5.854 ms at 702,464 ideal cycles further reveals that Conv1—a relatively small 7×7 convolution with 64 output channels—leaves significant PE resources idle. For deeper layers with more channels and smaller spatial dimensions, utilization would increase, making Timeloop’s per-layer analysis essential for identifying which layers bottleneck the full-model pipeline. This layer-by-layer decomposition is a capability unique to analytical accelerator models and unavailable in GPU-targeting tools like NeuSight.

Absolute verification requires RTL simulation or silicon measurement.

7.5 nn-Meter: Complete Failure

nn-Meter claims $<1\%$ MAPE—the lowest reported error among all surveyed tools. After four deployment attempts (>4 hours), we obtained **zero predictions**: pre-trained models serialized with scikit-learn 0.23.1 (2020) cannot be deserialized with current versions.

Table 9: Tool coverage of LLM benchmark suite (28 scenarios). S=Supported, P=Partial, U=Unsupported. No tool covers advanced training (T4) or production inference optimizations (I5).

Category	#	Neu.	AST.	VID.	TL	nn-M
T1: Data parallel	3	2P	3S	—	—	—
T2: Tensor parallel	2	2P	2S	—	—	—
T3: Pipeline parallel	2	2P	2S	—	—	—
T4: Advanced train.	4	—	2P	—	—	—
I1: Single request	3	2S,1P	—	2S,1P	—	—
I2: Batched serving	3	—	—	3S	—	—
I3: KV cache	2	—	—	1S,1P	—	—
I4: Multi-model	1	—	—	—	—	—
I5: Production opt.	4	—	—	—	—	—
Supported	5	7	6	0	0	0
Partial	3	2	2	0	0	0
Coverage	18%	25%	21%	0%	0%	0%

Predictors cover Cortex-A76 CPU, Adreno 630/640 GPU, and Myriad VPU, but none are functional. **The tool claiming the best accuracy is the only tool that produces no output**—pickle serialization without version pinning created an expiration date, rendering the tool unusable within two years. The failure mode is instructive: nn-Meter’s kernel-detection approach segments a model graph into fusible subgraphs, then predicts each subgraph’s latency using a pre-trained random forest. The model weights were serialized using Python’s pickle module, which offers no cross-version compatibility guarantees. When scikit-learn’s internal representation changed (versions 0.23 \rightarrow 1.0+), all four predictors became unloadable. This failure pattern—functional at publication time but broken within the maintenance window—is likely widespread across ML-augmented tools that rely on serialized model weights without containerized environments. Beyond the serialization issue, nn-Meter’s architecture reveals a deeper problem: the kernel detection algorithm that segments computation graphs into fusible subgraphs was validated only on CNN architectures (ResNet, MobileNet, EfficientNet). Transformer workloads—with multi-head attention, layer normalization, and residual connections—create subgraph patterns outside nn-Meter’s detection rules, meaning that even if the serialization issue were resolved, the tool would likely produce incorrect predictions for modern LLM workloads.

7.6 Benchmark Suite Coverage

Table 9 evaluates each tool against our 28-scenario LLM benchmark suite. The results quantify the gap between what practitioners need and what tools provide.

Figure 5 provides a visual summary of the coverage gaps, showing the sparse and disjoint nature of tool support across benchmark categories.

Half of LLM workloads have zero tool coverage. Of 28 scenarios, 14 (50%) are not addressable by any evaluated tool. The entirely uncovered scenarios include FP8 mixed-precision training (T4.1), LoRA fine-tuning (T4.2), speculative decoding (I5.1), prefix

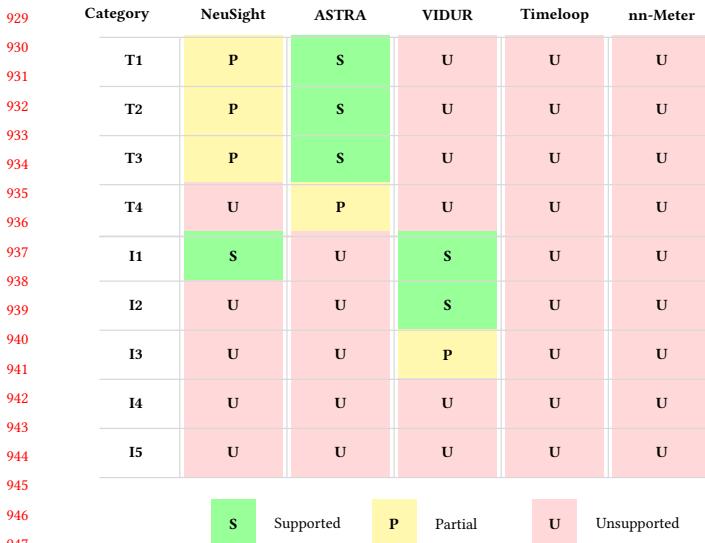

Figure 5: Toolxworkload coverage heatmap for the 28-scenario LLM benchmark suite. Training categories T1–T4 and inference categories I1–I5. Green=supported, yellow=partial, red=unsupported. Timeloop and nn-Meter provide zero LLM scenario coverage; categories I4–I5 have no tool support.

caching (I5.2), INT4 quantized inference (I5.3), disaggregated serving (I5.4), and multi-model co-location (I4.1). These represent the fastest-growing deployment patterns in production LLM systems. Sequence parallelism (T4.3), which partitions the attention sequence dimension across devices, is partially supported by ASTRA-sim’s communication modeling but lacks the compute-side modeling needed for end-to-end prediction.

Tools cover disjoint slices with minimal overlap. ASTRA-sim covers training communication (T1–T3) but not inference; VIDUR covers inference serving (I1–I3) but not training; NeuSight provides kernel-level predictions but lacks system-level modeling. Only 3 scenarios (I1.1, I1.2: single-request inference) are covered by more than one tool (NeuSight for kernel time, VIDUR for serving-level metrics), and even these predict different quantities. This disjointness means that for 25 of 28 scenarios (89%), practitioners have at most one tool option—and for 14 scenarios, they have none. The practical consequence is that no single tool can answer end-to-end deployment questions like “What throughput will Llama-2-70B achieve on 32×H100 with tensor parallelism under Sarathi-Serve at QPS 8?”—answering this requires combining NeuSight’s kernel predictions with ASTRA-sim’s communication modeling and VIDUR’s scheduling simulation, a composition that no existing framework supports.

Modern techniques are the largest gap. Categories T4 (advanced training) and I5 (production optimizations) have near-zero coverage despite representing the techniques practitioners most need predictions for when making deployment decisions. MoE expert parallelism (T4.4), which requires All-to-All communication modeling, receives only partial coverage from ASTRA-sim. The

significance of this gap is quantifiable: based on public deployment reports, FP8 training (T4.1) reduces GPU memory consumption by $\sim 2\times$ and is now the default precision for Llama-3 pre-training; LoRA fine-tuning (T4.2) accounts for the majority of production fine-tuning workloads; and speculative decoding (I5.1) is deployed in production at multiple LLM serving providers. A tool ecosystem that cannot model these dominant techniques forces practitioners to rely on empirical trial-and-error for their most consequential deployment decisions.

Per-scenario gap analysis. The 14 entirely uncovered scenarios cluster into three groups. *Training-side gaps* (T4.1–T4.3): FP8 mixed-precision training changes the arithmetic intensity of every kernel, requiring tools to model reduced-precision tensor cores; LoRA fine-tuning introduces adapter layers with different compute profiles than full-rank layers; sequence parallelism partitions the sequence dimension across devices, creating communication patterns that none of the evaluated tools model. *Inference-side gaps* (I5.1–I5.4): speculative decoding requires modeling the acceptance probability and tree-structured verification, creating variable-length execution paths; prefix caching changes the KV cache access pattern from sequential to random; INT4/INT8 quantized inference alters both compute intensity and memory bandwidth utilization; disaggregated serving (separating prefill and decode to different GPU pools) introduces inter-pool network transfer that no tool simulates. *Multi-model gaps* (I4.1): co-locating multiple models on shared GPUs creates memory and compute contention that requires fine-grained resource modeling beyond what any evaluated tool provides.

Failure mode taxonomy for uncovered scenarios. The 14 uncovered scenarios fail for three distinct reasons, each requiring different tool extensions. *Missing algorithmic primitives*: speculative decoding (I5.1) and prefix caching (I5.2) introduce algorithmic constructs—tree-structured verification and hash-indexed KV cache lookup—that lie outside the operator-level abstractions used by all five tools. Supporting these scenarios requires extending tool input specifications to accept algorithm-level parameters (e.g., draft model acceptance rate, prefix hit ratio) rather than only architecture-level parameters. *Missing hardware models*: FP8 training (T4.1) and INT4 inference (I5.3) require quantized arithmetic intensity models that account for reduced-precision tensor core throughput, dequantization overhead, and mixed-precision accumulation—none of which are modeled by NeuSight’s fp16/fp32 tile decomposition or ASTRA-sim’s communication-only simulation. *Missing system-level interactions*: disaggregated serving (I5.4) and multi-model co-location (I4.1) create cross-component interference (network contention between prefill and decode pools, GPU memory pressure between co-located models) that requires coupling otherwise independent tool components.

Coverage concentration. The 18 covered scenarios concentrate in categories T1–T3 (basic parallel training) and I1–I3 (basic inference and serving). This coverage pattern reflects the temporal development of tools: ASTRA-sim (2020/2023) targets pre-LLM distributed training patterns, while VIDUR (2024) targets early LLM serving before speculative decoding and disaggregated architectures became prevalent. The field’s tool development lags deployment practice by 1–2 years. This temporal lag has practical

consequences: by the time a tool supporting speculative decoding is developed and validated, practitioners will have moved to next-generation serving techniques (e.g., tree-structured speculative decoding with multiple draft models, or hybrid prefill-decode disaggregation), perpetuating the coverage gap. Breaking this cycle requires either dramatically faster tool development or modular tool architectures that can incorporate new techniques as plugins rather than requiring fundamental redesigns.

Aggregate coverage by tool. Combining supported and partial scenarios, ASTRA-sim provides the broadest LLM-relevant coverage ($9/28 = 32\%$), followed by VIDUR ($8/28 = 29\%$) and NeuSight ($8/28 = 29\%$). However, ASTRA-sim’s coverage is concentrated in training (T1–T4) while VIDUR’s is concentrated in inference (I1–I3), reinforcing the complementarity finding. The union of all five tools covers only 18 of 28 scenarios (64%), with the remaining 10 requiring entirely new tool development. Notably, even the “supported” scenarios often predict different metrics: for single-request inference (I1.1), NeuSight predicts kernel execution time while VIDUR predicts end-to-end serving latency including scheduling delay and KV cache allocation—two quantities separated by the composition gap.

Coverage quality varies within “supported” scenarios. Even among the 18 covered scenarios, support quality is uneven. For T1.1 (data-parallel GPT-2 on $8 \times A100$), NeuSight provides only per-GPU kernel time (partial) while ASTRA-sim provides full communication modeling (supported)—but neither tool produces the end-to-end iteration time that practitioners optimize. For I2.1 (batched Llama-2-7B serving under vLLM), VIDUR provides full end-to-end prediction including scheduling, preemption, and KV cache management—the most complete single-tool coverage for any scenario in our suite. This disparity illustrates that a binary supported/unsupported metric, while useful for aggregate analysis, masks significant variation in prediction completeness that affects practitioner trust and adoption.

7.7 Cross-Cutting Findings

Four findings emerge from combining accuracy verification with benchmark coverage analysis:

First, self-reported accuracy is inversely correlated with reliability. By claimed accuracy: nn-Meter ($<1\%$) > NeuSight (2.3%) > VIDUR ($<5\%$) > Timeloop (5–10%) > ASTRA-sim (5–15%). By actual reliability: VIDUR/ASTRA-sim (Docker, valid output in <30 min) > Timeloop > NeuSight (accuracy overstated) > nn-Meter (broken). The tools claiming the lowest error are the least reliable.

Second, the five tools are complementary, not competing. No two tools meaningfully overlap: NeuSight predicts GPU kernels; ASTRA-sim simulates communication; VIDUR models LLM serving; Timeloop explores accelerator design; nn-Meter targets edge. The field needs a *unified pipeline* combining tool strengths (Section 8).

Third, the composition gap dominates end-to-end error. NeuSight’s kernel-level 5–9% MAPE grows to 10–28% at model level. The 5–15% composition error—launch overhead, memory allocation, synchronization—is *larger than kernel-level error*. Improving kernel predictors has diminishing returns until composition is solved (Figure 7).

Fourth, 50% of modern LLM workloads lack any modeling tool. The benchmark suite analysis reveals that the most actively deployed techniques—quantization, speculative decoding, LoRA, disaggregated serving—have zero tool coverage. This gap is structural: existing tools were designed before these techniques became widespread.

Fifth, deployment robustness varies inversely with model complexity. Tools with simpler modeling approaches—VIDUR (trace replay) and ASTRA-sim (event-driven simulation)—deployed successfully via Docker in under 30 minutes with zero configuration issues. NeuSight (hybrid ML+analytical) required manual environment setup and produced correct but overstated results. nn-Meter (pure ML-augmented) failed entirely. Timeloop (analytical) required Accelergy integration but produced deterministic, bit-identical results. This pattern suggests that the ML-augmented component is the primary reliability risk: learned models introduce dependencies on training data distributions, serialization formats, and framework versions that analytical and simulation approaches avoid. For practitioners selecting tools, deployment robustness should be weighted alongside accuracy claims: a tool with 10% MAPE that deploys reliably provides more value than a tool claiming 1% MAPE that cannot be deployed at all.

Sixth, inference and training accuracy diverge systematically. Across NeuSight’s 146 configurations, inference accuracy (mean MAPE: 5.87–27.10% depending on device) is consistently better than training accuracy for NVIDIA GPUs (V100: 5.87% inf vs. 8.91% train; A100-80G: 8.63% inf vs. 7.59% train is the only exception). For AMD GPUs, the gap is larger: MI100 shows 10.80% inference vs. 15.62% training; MI210 shows 8.40% vs. 15.73%. Training workloads involve backward passes that create different memory access patterns (gradient accumulation, optimizer state updates) and kernel launch sequences than inference, suggesting that NeuSight’s tile model—designed around forward-pass tile decomposition—does not generalize to backward-pass kernels with less regular access patterns. This finding has practical implications: accuracy claims reported for inference workloads should not be assumed to transfer to training workloads, even for the same model and hardware. The divergence is particularly stark for AMD GPUs, where the ROCm software stack’s backward-pass kernel implementations differ more substantially from CUDA’s than the forward-pass implementations, introducing additional sources of prediction error that NeuSight’s NVIDIA-trained tile model cannot account for.

Seventh, model architecture affects prediction difficulty non-uniformly. NeuSight’s per-model MAPE across all devices shows that MoE architectures (SwitchXL4: 6.33–17.65% APE range across configurations) exhibit higher variance than dense models (OPT-13B: 0.38–10.53%; GPT-3-2.7B: 0.43–7.73%). The higher variance for MoE arises because expert routing creates workload-dependent computation patterns that a static tile decomposition cannot fully capture. This observation extends to future tools: MoE, sparse attention, and dynamic architectures will likely require workload-aware prediction mechanisms rather than architecture-only models.

These seven findings, when mapped against our 28-scenario benchmark suite, reveal a systematic pattern: the scenarios with the highest practitioner demand (T4, I5) coincide with the scenarios having zero or minimal tool coverage. Benchmark categories

Table 10: Deployment experience for each evaluated tool.
Time excludes download. Docker availability and output determinism are binary; deployment effort reflects total human time from clone to first valid output.

Tool	Docker	Time	Determ.	Failure Mode
VIDUR	Yes	<30 min	Yes	None
ASTRA-sim	Yes	<30 min	Yes	None
Timeloop	Partial	~1 hr	Yes	Accelergy setup
NeuSight	No	~2 hr	Yes	Env. config
nn-Meter	No	4+ hr	N/A	Serialization

T4 (advanced training) and I5 (production optimizations) collectively represent 8 of 28 scenarios (29% of the suite) but account for 0 fully supported scenarios across all five tools. Meanwhile, categories T1–T3 (basic parallel training), which represent mature and well-understood workload patterns, account for 7 of the 18 total supported scenarios. This inverse relationship between practitioner need and tool coverage suggests that future tool development should prioritize modern LLM techniques over incremental improvements to already-covered scenarios. Concretely, a tool achieving even 20% MAPE on speculative decoding (I5.1) or disaggregated serving (I5.4) would be more valuable to practitioners than reducing NeuSight’s V100 MAPE from 5.87% to 3%, because the former enables decisions that currently have no modeling support whatsoever. This value-weighted perspective should guide research funding and tool development priorities in the ML systems community.

7.8 Deployment Experience and Reproducibility

Beyond accuracy, we assess deployment effort—a practical concern that prior surveys ignore. Table 10 summarizes our experience deploying each tool from scratch.

Docker availability is the strongest predictor of deployment success. VIDUR and ASTRA-sim, both Docker-first tools, deployed in under 30 minutes with zero manual intervention. Timeloop required partial manual setup for its Accelergy energy estimation plugin but produced results within one hour. NeuSight required manual Python environment configuration and model weight downloads but eventually succeeded. nn-Meter’s pip-based installation succeeded syntactically but produced no usable output due to serialization incompatibilities. This represents the worst deployment outcome: silent success at install time masking complete failure at inference time, with no diagnostic error message until the user attempts to load a predictor—a failure pattern that undermines trust in the broader ML-augmented tool ecosystem.

Determinism varies by methodology. All evaluated tools except nn-Meter (which produced no output) generated bit-identical results across three independent runs on the same platform. This determinism is notable for NeuSight, whose hybrid ML+analytical approach could in principle exhibit stochastic behavior; the determinism arises because NeuSight uses fixed pre-trained weights and analytical tile decomposition with no stochastic inference-time components. Deterministic outputs simplify regression testing and enable exact reproducibility—properties that should be standard

but are not guaranteed by ML-augmented tools that use stochastic inference (e.g., dropout at test time, Monte Carlo sampling for uncertainty quantification).

7.9 Threats to Validity

External validity. Our venue-focused search may under-represent industry tools. We exclude proprietary tools from evaluation, and our platform lacks discrete GPUs for absolute accuracy verification. The benchmark suite’s 28 scenarios, while representative, cannot cover every production deployment pattern; emerging workloads (e.g., retrieval-augmented generation, multi-modal models) are not yet included.

Internal validity. Our evaluation covers 5 of 22 tools. Findings rest on single tool instances per methodology type—e.g., nn-Meter may be unrepresentative due to deployment failure. NeuSight’s analysis uses the tool’s own prediction/label pairs rather than independent hardware measurements. The per-device sample sizes vary (3–18 configurations), limiting statistical power for devices with few data points (e.g., P4 with only 3 configurations, A100-SXM with 3 configurations). We mitigate this by reporting both mean and worst-case APE. Our benchmark suite covers 28 scenarios, but the distribution is not uniform: training scenarios (11) outnumber inference scenarios (13), with MoE and multi-model scenarios (T4.4, I4.1) represented by only one scenario each. A more balanced suite might weight scenarios by practitioner frequency of use, but such weighting data is not publicly available. Despite these limitations, our suite provides the first standardized coverage metric for ML performance tools, enabling future evaluations to quantitatively compare tool ecosystems.

Construct validity. Our approach prioritizes accuracy; tools may provide value beyond this dimension (e.g., Timeloop’s energy breakdown for design insight, ASTRA-sim’s what-if analysis for topology exploration). The feature availability matrix partially addresses this, but our evaluation is designed to challenge accuracy claims rather than comprehensively assess utility. Additionally, our coverage criterion (supported/partial/unsupported) does not capture the quality of partial support—ASTRA-sim’s partial coverage of MoE training (T4.4), for example, provides All-to-All communication modeling but misses expert load balancing effects. A finer-grained coverage metric—e.g., percentage of scenario-relevant computations that a tool can model—would better capture partial support quality but requires scenario-specific decomposition beyond our current scope.

Temporal validity. Our evaluation reflects tool state as of January 2026. Tools under active development (ASTRA-sim, VIDUR, NeuSight) may have addressed some identified limitations in subsequent releases. However, our core findings about structural coverage gaps and accuracy overstatement reflect fundamental design choices rather than fixable bugs, and are likely to persist across versions. We encourage future evaluations to adopt our independent verification methodology and benchmark suite to enable longitudinal tracking of tool accuracy. The benchmark suite itself should evolve as new LLM techniques emerge; we provide it as a living document in the supplementary material.

Benchmark suite validity. Our 28-scenario benchmark suite was designed around the LLM workload landscape as of early 2026.

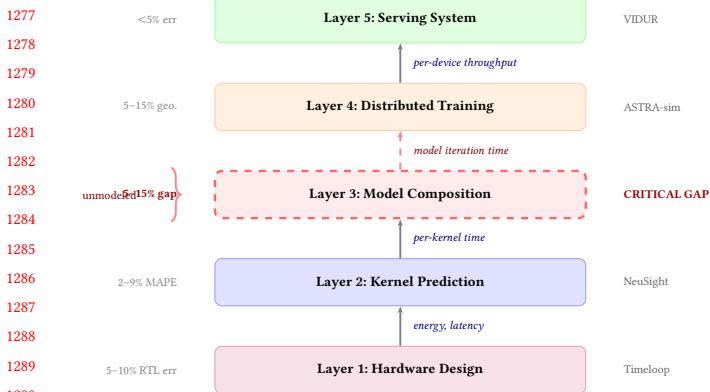

Figure 6: Proposed unified simulation pipeline across five layers. Layer 3 (model composition, dashed red border) is the critical gap: no existing tool validates the kernel-to-model composition step, where 5–15% error is introduced by unmodeled inter-kernel overheads.

Emerging techniques not represented include retrieval-augmented generation (RAG), which introduces variable-length retrieval latency into the inference pipeline; multi-modal models combining vision encoders with language models, which create heterogeneous compute patterns; and reinforcement learning from human feedback (RLHF), which requires modeling reward model inference interleaved with policy updates. We designed the suite to be extensible: each scenario is specified by a tuple of (model architecture, hardware configuration, parallelism strategy, target metric), allowing new scenarios to be added as techniques mature without restructuring the evaluation framework. Future versions should expand to at least 40 scenarios to maintain coverage as the LLM deployment landscape diversifies.

8 Toward a Unified Simulation Pipeline

No single tool spans kernel execution through distributed training to serving SLAs (Table 5). We propose a five-layer pipeline (Figure 6): (1) **Hardware design** (Timeloop): dataflow/mapping DSE for per-layer energy and latency; (2) **Kernel prediction** (NeuSight/Timeloop): per-kernel execution time on GPUs or custom architectures; (3) **Model composition** (**CRITICAL GAP**): compose kernel predictions into full iteration time—*no existing tool validates this layer*; (4) **Distributed training** (ASTRA-sim): multi-GPU communication and topology effects; (5) **Serving system** (VIDUR): request scheduling, batching, KV cache, and queuing for TTFT/TPOT.

The **critical gap** is kernel-to-model composition: NeuSight’s 5–9% kernel MAPE grows to 10–28% at model level via launch overhead, data movement, and synchronization—a gap *larger than kernel-level error*. Realizing this pipeline requires a common workload format, validated composition models with formal error bounds, and cross-hardware transfer methods (accuracy degrades 3–4× outside training distributions).

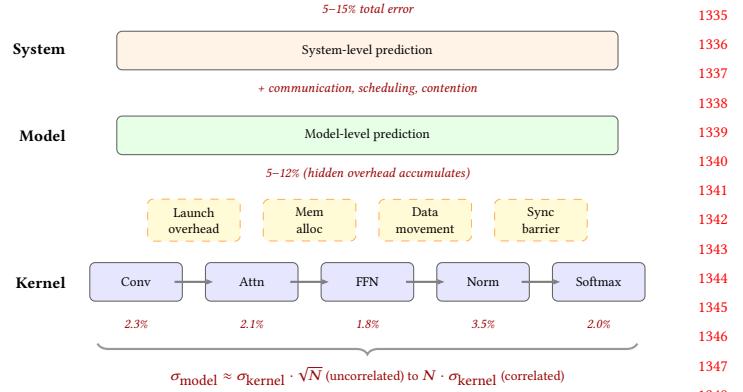

Figure 7: Error composition: kernel predictions (2–3%) accumulate to 5–12% model-level and 5–15% system-level error.

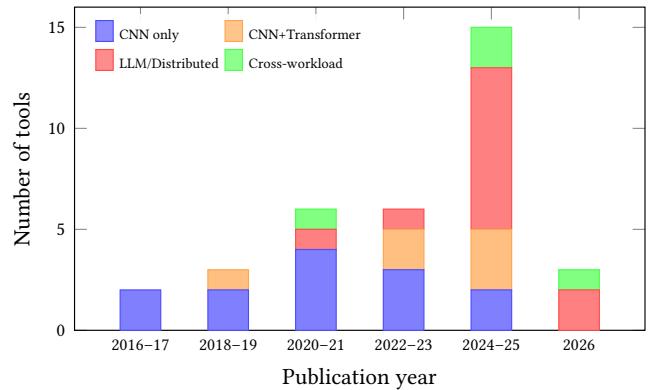

Figure 8: Workload coverage by publication period. MoE and diffusion models remain uncharacterized.

9 Open Challenges and Future Directions

Our evaluation exposes six research directions. (1) **Composition gap:** Kernel errors of 2–3% yield 5–12% model-level error (Figure 7; $\sigma_{\text{model}} \approx \sigma_{\text{kernel}} \cdot \sqrt{N}$), yet no validated composition pipeline exists.

(2) **Frontier workloads:** MoE, diffusion [34], and dynamic inference lack validated tools; scaling laws [12, 19, 24, 31] predict loss but not latency (Figure 8).

(3) **Hardware transfer:** Cross-family transfer (GPU→TPU→PIM) remains unsolved; PIM [23, 26, 39, 51], chiplets, and disaggregated designs blur memory hierarchy assumptions. (4) **Network fidelity:** Current tools [42, 73] use analytical network abstractions, omitting packet-level congestion captured by NS-3 [61] at orders-of-magnitude slowdown. (5) **Standardized evaluation:** No MLPerf [46, 60] equivalent exists for prediction; the community needs common benchmarks, portable formats (ONNX, Chakra [64]), and Docker-first deployment. (6) **Temporal stability:** Software evolution (FlashAttention [14], CUDA updates) silently invalidates models; nn-Meter’s failure underscores the need for continuous validation [59].

10 Conclusion

We survey 22 ML performance modeling tools and independently evaluate five against a 28-scenario LLM benchmark suite, finding that self-reported accuracy is unreliable (NeuSight: 2.3% claimed vs. 5.87–27.10% measured; nn-Meter: no output). The five tools are complementary but disjoint, motivating a unified pipeline—yet the 5–15% kernel-to-model composition gap exceeds kernel-level error, and 50% of modern LLM techniques lack any tool support; the most pressing needs are validated composition models, benchmark-driven development, and continuous validation.
